MS received 5 October 1995; revised 8 April 1996

Abstract. In this paper, histopathological changes in the inner lining of the accessory respiratory organ of Heteropeustes fossilis following exposure to sublethal concentration (0·2 g l⁻¹) of ammonium sulphate (3 mg l⁻¹ total ammonia-N) has been described. The goblet cells show periodic increased followed by decreased secretory activities. Necrosis and shedding of the epithelial cells over the secondary lamellae cause periodic haemorrhages which lead to degeneration and decreased number of secondary lamellae. Subsequently regeneration takes place each time as evidenced by the appearance of inflammatory tissue. Fusion of more than one secondary lamellae is also common. Regeneration also leads to uncontrolled hyperplasia of haphazardly arranged epithelial cells. This hyperplasia causes increased distance of respiratory blood-air barrier in the secondary lamellae, leading to impaired normal aerial respiration.

Keywords. Heteropeustes fossilis; accessory respiratory organ; ammonium sulphate toxicity; histopathology.

1. Introduction

Gills, skin, liver, kidney, thyroid, intestine and gonads are among the few extensively studied organ systems of fishes, exposed to various concentrations of ammonia (both NH₃ and NH₄⁺) (Mukherjee and Bhattacharya 1975; Sathyanesan et al 1978; Smith and Piper 1975; Joy and Sathyanesan 1977; Chatterjee and Bhattacharya 1983; Thurston et al 1984; Ram and Sathyanesan 1986, 1987a; Bhattacharya et al 1989; Wright et al 1989; Banerjee and Paul 1993). Contamination of waterbodies with ammonia takes place during applications of the inorganic fertilizer, ammonium sulphate, both for agricultural as well as aquacultural purposes (Jhingran 1983; Ram and Sathyanesan 1987b; Sarkar 1991; Varadachari 1992). The live fish Heteropeustes fossilis (Bloch), an important edible catfish is a bimodal breather because it can respire aerially by gulping in air at various intervals when oxygen content of water is reduced below saturation point (Munshi 1993). A pair of sac-like backward extensions from the supra branchial chamber (derived from the embryonic gill mass), embedded deeply into the body myotomes, one on each side of the body are the main parts of the air breathing organs (accessory respiratory organ, ARO) in this fish (Munshi 1962, 1993) which unlike gills, does not come under the direct contact of the external medium. Hence in this paper, efforts have been made to analyse the toxicity of sublethal concentration of

*Corresponding author (Fax, 0542-312059).
ammonium sulphate on the inner epithelial lining (respiratory epithelium) of the ARO of H. fossilis because the toxic manifestation of the xenobiotics is affected in this vital organ via the circulatory system.

2. Materials and methods

2.1 Fish and their maintenance

Healthy specimens of H. fossilis of either sex belonging to a single population (body length 16–18 cm and body weight 35–40 g), collected at Varanasi were maintained in large plastic aquaria bearing 501 of tap water for one month for acclimation. They were fed with minced goat liver on every alternate day. Water was renewed after every 24 h.

2.2 LC_{50} calculation

Prior to the commencement of the experiment, 96 h median lethal concentration (96 h LC_{50}) of ammonium sulphate (99% pure, E Merck India Ltd., Bombay) was estimated following trimmed Spearman-Karber method (Hamilton et al. 1977) and 24 h renewal bioassay system, which was found to be 2 g l^{-1} after 5% trimming.

2.3 Experimental protocol

Five groups of ten fish each were exposed to 50 l of 0.2 g l^{-1} (10% of the 96 h LC_{50}) ammonium sulphate (3 mg l^{-1} total ammonia nitrogen) (APHA et al. 1985) solution prepared in tap water (having dissolved oxygen 6 mg l^{-1}, pH 7.5, hardness 23.2 mg l^{-1} and water temperature 26 ± 2°C). Parallel controls under similar conditions but without the addition of ammonium sulphate were also maintained. Both the media (experimental as well as control) were renewed after every 24 h. Feeding was allowed for a period of 2 h on every alternate day before the renewal of the media. No mortality was observed at any stage of exposure.

2.4 Histopathological analysis

Five experimental and five control fish were sacrificed by cervical dislocation after the expiry of 5, 10, 20, 30 and 45 days of exposure. One cm long fragments of the ARO from the anterior end were fixed in 10% neutral formalin, aqueous Bouin’s fluid and Helly’s fluid. Permanent whole mount preparations as well as 6 μm paraffin sections were stained with Ehrlich’s haematoxylin/eosin for general toxicopathological analysis. Glycoproteins were localized by alcian blue pH 2.5 (AB 2.5) (Pearse 1985) and periodic acid Schiff (PAS) (McManus 1946) and AB 2-5/PAS dual staining (Pearse 1985). Sulphated acidic mucopolysaccharides were localized by alcian blue pH 1-0 (AB 1.0) (Lev and Spicer 1964). Bismarck brown technique was employed for water stable mucoproteins (Leech 1947). PAS with prior treatment with salivary amylase was used to confirm the presence of glycogen (Pearse 1985).
3 Results and discussion

2 Control accessory respiratory organ

The innermost lining of the thin walled ARO of *H. fossilis* is a multilayered epithelium, next to which serially arranged are basement membrane, connective tissue layer, a thin membrane and a thin muscular coat (figure 1). Vascular and non-vascular areas constitute the inner epithelial lining. The vascular areas are represented by islets of secondary lamellae of various dimensions (Munshi 1962) (figure 2). An islet (primary lamellae) is formed by double row of modified secondary gill lamellae that hang into the lumen of ARO. In transverse sections (TS) these secondary lamellae appear as vertical strands penetrating perpendicularly into the multilayered epithelium (figure 3). Often on TS, these lamellae bulge out into the lumen as finger-like projections. In whole mount preparations the tips of the secondary lamellae appear to project into the lumen. Each secondary lamellae is made up of stacks of serially arranged pillar cells (figure 1). In between the pillar cells definite blood channels are formed. The non-vascular area of the epithelial lining is made of several layers of epithelial cells (ECs) in between which are lodged a number of large sized mucous cells (MCs) (figure 3). A thin slimy layer of PAS negative and AB 2-5 positive material occasionally covers the inner surface at certain places. The moderately PAS positive basement membrane courses into the epithelium along with the secondary lamellae (figure 3).

3.2 Experimental accessory respiratory organ

Five days after exposure the density (number) of MCs decreases and the finger like secondary lamellae bulge out distinctly, projecting prominently into the lumen of the ARO (figure 4). The basement membrane of the epithelium and secondary lamellae stain markedly with PAS technique. The distal ends of the swollen banana shaped secondary lamellae bulge out further to acquire club shape which also get engorged with red blood cells. At certain places, the epithelial lining becomes degenerate and sloughs off (figure 4). Focal inflammatory tissues which represent sites of active healing and re-differentiation of lamellar structures, are noticed at this stage of exposure. Similar inflammatory foci (granulation tissues) were also observed at the healing sites of superficial skin wounds by Mittal and Munshi (1974) and Mittal *et al* (1979). Even though the blood capillaries stain prominently with PAS, the inflammatory tissue stains negatively for glycoproteins and other acidic mucosubstances. Minute developing MCs are occasionally noticed in the regenerating epithelial tissue over the inflammatory tissue. A few fine glycogen granules are also noticed in the undifferentiated inflammatory tissue.

With AB 2-5, the intensity of reaction in MCs decreased markedly up to 20 days of exposure. The intensity, however, increases after 30 days and with further treatment, when the entire volume of the MCs stained strongly. After 10 days, the inflammatory tissue disappears probably due to completion of regeneration following differentiation of various elements of the damaged ARO. The newly regenerated epithelium shows hyperplasia of haphazardly arranged ECs with poorly formed secondary lamellae (figure 5).

Regeneration of secondary lamellae continues after 20 days with swelling again to become prominent. Fusion of more than one secondary lamellae are commonly
Figures 1–9.
observed along with the accumulation of blood at the tips of the club-shaped secondary
lamellae. Similarly, prominent inflammatory tissues are again observed in the
epithelial area after 30 days of exposure (figure 6). Re-appearance of the inflamma-
tory tissue after 30 days suggests active process of healing of certain severely damaged
areas on the inner lining of the air-sac. The highly vascular inflammatory tissue in the
epithelial region below the newly regenerated epithelium is marked by the presence
of numerous red blood corpuscles (RBCs). Well defined (regenerated) blood capillaries
to enclose the RBCs are not properly located. However, secondary lamellae are
observed in undamaged epithelia during this period of exposure. After 45 days these
lamellar structures become well formed and prominently exposed. Side by side
shedding of ECs causing haemorrhage and leaking of blood into the lumen and fusion
of secondary lamellae (figure 7) are again noticed due to continuation of treatment.

Like the acute ammonia exposure (Paul and Banerjee 1995), the density and staining
properties of MCs during the present investigation also exhibit periodic fluctuations
(figures 8, 9 and table 1). At different stages of exposure, periodic fluctuations in the
quantity of glycogen granules are also observed (table 1). There is a marked decrease in
the quantity of glycogen after 10 days followed by an increase after 20 days. Thereafter
the decreasing trend continues and disappear completely after 45 days.

Even though the ARO is not directly exposed, the periodic fluctuations observed in
the secretory activity of MCs in the present study is more or less identical to those
observed in gills and skin of fishes (Roy 1988; Roy et al 1993). Similar fluctuations have
also been noticed in the MCs of ARO following treatment with toxic heavy metal salts
(Rajan and Banerjee 1992; Hemalatha and Banerjee 1993). Although, the exact reason for
the fluctuation is not properly understood especially when the ARO is not getting
exposed directly to the xenobiotic, it might perhaps be due to the common origin of the
ARO and the gills (Munshi 1993). The ARO also shows fusion of its secondary lamellae
similar to those observed in gills following exposure to the ammonia solution (Smith
and Piper 1975) as well as other toxicants (Leino et al 1987). Even though the ARO
does not suffer the contact stress, erosion of the epithelial lining and alterations in the
chemical composition of mucus are prominently observed in the ARO following
ammonium sulphate exposure. This could perhaps be the reason for fusion of sec-
ondary lamellae. Because, according to Daoust et al (1984) the lamellar adhesion in gills
might be due to contact stress which causes erosion and consequent alteration in the

Histopathology of accessory respiratory organ

Chemical composition and thickness of the mucous layer after interaction with antimicrobics. This disturbs the normal ability to recognize different cell types resulting in regression of the secondary lamellae.

Formation of inflammatory tissue in the sub-epithelial layer at different stages of exposure indicates active and repeated healing and regeneration of lamellar elements from the severely damaged sites. This shows that severe toxicity has been rendered to the deeply embedded respiratory organ by the ammonia solution even at sublethal concentration causing disturbed aerial respiration. While studying the chronic toxicity of ammonia to Fathead Minnows (Pimephales promelas), Thurston et al. (1986) also observed deep-seated mild to severe lesions of connective tissues (connective tissue hyperplasia), originating from the Meninx primativa, covering the brain and termed it as proliferating tissue. Blood vessels were also observed throughout the proliferated tissue. These proliferated tissues also stained negatively for collagen, mucin and mucopolysaccharides (Smith, 1984).
