A third or more of the fixed nitrogen lost from the oceans as N$_2$ is removed by anaerobic microbial processes in open ocean oxygen minimum zones. These zones have expanded over the past decades, and further anthropogenically-induced expansion could accelerate nitrogen loss. However, in the Bay of Bengal there has been no indication of nitrogen loss, although oxygen levels are below the detection level of conventional methods (1 to 2 $\mu$M). Here we quantify the abundance of microbial genes associated with N$_2$ production, measure nitrogen transformations in incubations of sampled seawater with isotopically labeled nitrogen compounds, and analyse geochemical signatures of these processes in the water column. We find that the Bay of Bengal supports denitrifier and anammox microbial populations, mediating low, but significant N loss. Yet, unlike other oxygen minimum zones, our measurements using a highly sensitive oxygen sensor demonstrate that the Bay of Bengal has persistent concentrations of oxygen in the 10 to 200 nM range. We propose that this oxygen supports nitrite oxidation, thereby restricting the nitrite available for anammox or denitrification. If these traces of oxygen were removed, nitrogen loss in the Bay of Bengal oxygen minimum zone waters could accelerate to global significance.
Oxygen deficient regions of the open ocean account for 20 to 40% of fixed nitrogen loss, while making up only approximately 1% (O₂ < 20 µM) of global ocean volume¹. Regions of nitrogen loss associated with oxygen depletion are presently recognized in the Eastern Tropical Pacific Ocean, off the coast of Namibia, and in the Arabian Sea¹,²,³. In this regard the Bay of Bengal (BoB) has proven an enigma, with no clear evidence for nitrogen loss despite oxygen depletion (< 2 µM O₂;⁴), although only geochemical indicators of nitrogen loss have been investigated to date in this region⁴,⁵,⁶.

We sampled the BoB in January 2014 during the winter monsoon (Figure 1 and S1). At five stations we measured oxygen in situ with a highly sensitive STOX sensor (switchable trace oxygen)⁷,⁸, with a limit of detection (LOD) of 7 to 12 nM. We used Niskin bottles to collect samples for nutrients, dissolved gases, nitrate isotopic analyses, molecular characterization of microbial populations and for experiments exploring aerobic and anaerobic microbial nitrogen metabolism.

**Oxygen levels and microbial populations in Bay of Bengal**

STOX oxygen data revealed sub-micromolar oxygen concentrations over a depth interval of about 200 meters throughout the study area (Figure 1). Only six single measurements were below the LOD, and these were confined to thin layers in the depth range between 280 and 360 m at Station 7 (Table S1). There was no evidence for distinct broad anoxic zones as seen in the other OMZs at any station, even at Station 1, where a secondary nitrite maximum of up to 180 nM was observed in the depth range 115 m to 150 m (Figure 1a; nitrite was at or below the LOD of 10 nM at all other stations analyzed). At this station, the lowest oxygen concentration was 36 nM at ~150 m (Figure 1 and Table S1). Persistent oxygen and low nitrite in the BoB contrasts with other major OMZs, which have anoxic cores (oxygen below STOX sensor detection) with > 500 nM nitrite⁹,¹⁰. When calibrated to the STOX data (Figure S2), a Seabird oxygen sensor revealed tremendous vertical structure in the oxygen profiles (Figure 1), indicating oxygen input by lateral intrusions.

Despite the lack of evidence for anoxia in BoB OMZ waters, the vertical zonation of microorganisms with nitrogen-metabolizing capabilities resembled typical OMZs supporting active N₂ production as indicated by 16S rRNA and functional gene abundances (Figure 2). Anammox bacteria, as quantified through their nitrite reductase gene (Scalindua nirS, or Sc nirS), were present within the OMZ waters, peaking at the depth of 150 m with about 1300 copies mL⁻¹, some 40 to 60% of the maximal abundance found in other OMZs with active N₂ production¹¹,¹². Nitrite reductase genes attributed to denitrifiers (Denitrifier nirS) were found at similar distribution and abundance to the Sc nirS, and were
even more abundant than in the Eastern Tropical South Pacific (ETSP) OMZ\textsuperscript{11, 13}. In addition, the distribution of functional genes of aerobic ammonium and nitrite oxidizers, thaumarchaeotal \textit{amoA} (Th \textit{amoA}) and \textit{Nitrospira/Nitrospina nxrB} (\textit{nxrB}) respectively, resembled the distributions in other OMZ waters\textsuperscript{11, 13, 14, 15}, where Th \textit{amoA} abundance peaks in the upper oxycline, here at about 80 m, and \textit{nxrB} abundance peaks lower in the water column where Sc \textit{nirS} is also most abundant. The similarity with other OMZs was further supported by the presence of the SUP05 clade, gammaproteobacterial sulfur oxidizers (GSO), and abundant adenylylsulfate (APS) reductase genes (\textit{aprA}), suggesting a role for sulfur cycling in the BoB OMZ waters\textsuperscript{16} (Figure S3).

**Activity of microbial nitrogen transformations**

Thus, microbial populations in BoB OMZ waters are capable of both anaerobic and aerobic nitrogen (and maybe sulfur) cycling as in other OMZs supporting N\textsubscript{2} production, despite a lack of any prior evidence for N\textsubscript{2} production. We performed parallel experiments with \textsuperscript{15}N-labeling to survey rates of microbial nitrate reduction and N\textsubscript{2} production in BoB OMZ waters (process rate experiments). With additions of \textsuperscript{15}NH\textsubscript{4}\textsuperscript{+} alone, anammox (NH\textsubscript{4}\textsuperscript{+} + NO\textsubscript{2}\textsuperscript{-} \rightarrow N\textsubscript{2} + 2H\textsubscript{2}O) rates were below detection (LOD 1.3 nM N d\textsuperscript{-1}) at all stations. Anammox rates of up to 6.2 nM N d\textsuperscript{-1}, however, were observed when NH\textsubscript{4}\textsuperscript{+} and NO\textsubscript{2}\textsuperscript{-} were added together, with labeling of either of the substrates (Figure 3a and S4). These potential rates are comparable to off-shore locations in the OMZs of the ETSP\textsuperscript{13} and Eastern Tropical North Pacific (ETNP)\textsuperscript{17}.

Anammox was also detected at rates of up to 5.5 nM N d\textsuperscript{-1} in separate experiments designed to explore the oxygen regulation of nitrite transformations (oxygen regulation experiments) where \textsuperscript{15}NO\textsubscript{2}\textsuperscript{-} was added alone (Figure 3b). Anammox activity decreased with increasing oxygen concentrations in three of the four experiments, but activity was observed up to our maximum concentration of 9.5 \textmu M, in line with a number of previous observations\textsuperscript{18}. Indeed, anammox rates remained high across the oxygen concentrations of the BoB OMZ. Summarizing our results, anammox was not measurable when ammonium was added alone, but was only detected with added nitrite. Thus, there is a large potential for N-loss via anammox in the BoB, but \textit{in situ} anammox bacteria are likely nitrite-limited rather than being limited by ammonium or inhibited by oxygen. Denitrification was below the LOD (2.7 nM N d\textsuperscript{-1}) in BoB OMZ waters in our process rate experiments (Figure 3A). We did, however, detect denitrification (up to 0.9 nM N d\textsuperscript{-1}) with \textsuperscript{15}NO\textsubscript{2}\textsuperscript{-} at Station 5 (but not Stations 1 or 4) in our oxygen regulation experiments with a lower median detection limit of 0.4 nM N d\textsuperscript{-1} (Figure 3b), suggesting a patchy
distribution of denitrification in BoB OMZ waters. When present, denitrification exhibited higher oxygen sensitivity than anammox (Figure 3b), with complete inhibition at O₂ concentrations above 4-5 µM (with a single point deviating from this trend), consistent with observations from the ETSP OMZ¹⁹.

Despite the low rates of anammox and denitrification, and the general absence of nitrite in BoB OMZ waters, we measured nitrite production rates from nitrate (¹⁵NO₃⁻) of up to 12.1 nM N d⁻¹ at Stations 4 and 5 (Figure 3a). We also measured potential nitrite oxidation rates of up to 52 nM N d⁻¹ in our oxygen regulation experiments (Figure 3b; Table S2). The presence of nitrite-oxidizing bacteria was confirmed by the detection of Nitrospira/Nitrospina-related nxrB sequences (Figure 2). The rates of nitrite oxidation exceeded those of nitrite production even at low oxygen concentrations, reaching maximum values at ~1 µM O₂, suggesting nitrite oxidizing bacteria have a high affinity for oxygen (Figure 3a) in agreement with recent observations²⁰. Our combined data indicate an active, coupled, anaerobic/aerobic nitrogen cycle where nitrate is reduced to nitrite and rapidly oxidized again to nitrate in the OMZ waters. A close coupling between nitrate reduction to nitrite and subsequent nitrite oxidation has also been described in the oxyclines of other OMZs, where nitrite also fails to accumulate despite active nitrate reduction to nitrite¹⁸, ²¹.

Thus, based on our experimental data, we conclude that the BoB OMZ oxygen concentrations (10 to 200 nM) limit N₂ production through anammox indirectly, by enabling aerobic nitrite oxidizing bacteria to outcompete anammox bacteria for the available nitrite. Denitrification was also not inhibited by the oxygen levels of BoB OMZ waters, but was generally low and only detected at two stations. Such patchiness may be related to the presence or absence of organic-matter rich aggregates in the incubations¹⁷.

**Geochemical evidence of nitrogen cycling**

Our molecular results and process rate measurements are supported by geochemical data that indicate a slow, but functioning, anaerobic nitrogen cycle in BoB OMZ waters. A small, albeit noisy, nitrogen deficit of 2 to 3 µM, indicative of net N loss, was calculated from our nutrient data (Figure 4 and Table S4). We also observed a maximum N₂ excess (calculated from N₂/Ar ratios) on the order of 2 to 3 µM N₂ in the OMZ waters (equivalent to 4 to 6 µM N). Throughout the sub-surface ocean, N₂ excess increases monotonically with depth due to abiotic factors²² but a local maximum within OMZs is strongly indicative of biogenic N₂ production²³. The δ¹⁵N of NO₃⁻ from the BoB OMZ showed small
enrichments of up to 1.5 ‰ relative to deep-water values consistent with net nitrate reduction. The larger
$^{18}$O enrichment in NO$_3^-$ of 3 ‰ is consistent with the coupled anaerobic/aerobic nitrogen cycle explored
above, with nitrate reduction to nitrite followed by reoxidation back to nitrate$^{24}$ (see SI). These three
geochemical indicators integrate over larger water volumes and over longer time scales than our rate
measurements, and, therefore, imply that nitrogen cycling and N$_2$ production are persistent phenomena
in the BoB, although these signals are smaller in magnitude than in other major OMZs$^{23, 24}$.

Taken together, our nitrogen deficit and N$_2$ excess measurements point to $\sim$2 $\mu$M of biologically
produced N$_2$ (4 $\mu$M N$_2$-N) in BoB OMZ waters. Previous studies have estimated annual water exchange
of 18×10$^{12}$ m$^3$ y$^{-1}$ in the depth interval from 150 to 250 meters, and 31×10$^{12}$ m$^3$ y$^{-1}$ in the interval from
250 to 500 m$^{25}$. We take 40% of the latter (12×10$^{12}$ m$^3$ y$^{-1}$) to estimate the exchange from 250 to 350 m,
obtaining a total annual water exchange of 30×10$^{12}$ m$^3$ y$^{-1}$ from 150 to 350 meters depth, and a turnover
time of 12 years for the 372×10$^{12}$ m$^3$ volume of this interval$^{25}$. This exchange rate, combined with a
biogenic N$_2$ excess of 2 $\mu$M, yields an annual production rate of $\sim$1.7 Tg N y$^{-1}$. This N$_2$ production is
about 12% of the production rate in the Arabian Sea, and some 2.5 % of the global water-column
production in OMZ settings (66±6 Tg N y$^{-1}$)$^{26}$.

This annual rate of N$_2$ production amounts to an average N$_2$ production rate of 0.88 nM-N d$^{-1}$ for the
volume between 150 to 350 m. As we were unable to measure N$_2$ production by anammox without
added nitrite, and as denitrification rates were low when detected at all (Figure 3), there must be either
seasonal or spatial variability in N$_2$ production that we have not captured in our process rate
experiments. Still, our process rate and oxygen regulation experiments (Figure 3) suggest a potential for
N$_2$ production of about 3 nM-N d$^{-1}$ under nitrite replete conditions, some 3.5 times greater than the
average rate calculated from the N$_2$ excess. Therefore, there is considerable potential for additional N$_2$
production in the BoB OMZ above that indicated from the geochemical indicators. As N$_2$ production,
particularly through anammox, is nitrite limited, the rates should increase if oxygen is depleted further,
suppressing nitrite oxidation and allowing nitrite to accumulate$^9$ in BoB OMZ waters. An accumulation
of nitrite in the sub-micromolar range may be sufficient to stimulate anammox substantially, judging
from the independence of anammox rates on nitrite concentrations across OMZs$^{27}$. If N$_2$ production
increased to an average of 3 nM-N d$^{-1}$ (as our experiments suggest), then N$_2$ production rates would
increase to about 6 Tg N y$^{-1}$ or about 40% of Arabian Sea rates and 9% of global water-column rates$^{26}$.
Such an increase would make the BoB an important player in the global nitrogen cycle.
The Bay of Bengal at a tipping point

The stable accumulation of nitrite in BoB OMZ waters would require the removal of the last traces of oxygen. The oxygen concentration reflects the dynamic balance between the processes mixing oxygen into the OMZ and the processes consuming it. An increase in the flux of organic matter to the OMZ waters would be one way to increase oxygen consumption, and an increase in primary production could accomplish this. Possible vehicles for increased primary production include the accelerated input of anthropogenic nitrogen into the BoB, as projected for the coming decades\textsuperscript{28} and changing intensity of the summer monsoon. In particular, the high southwesterly summer monsoon winds generate coastal upwelling, producing high concentrations of chlorophyll \textit{a}\textsuperscript{29} and enhanced oxygen depletion in coastal waters\textsuperscript{30}. Therefore, accelerated summer monsoon intensity could potentially increase the flux of organic matter to OMZ waters, drawing down oxygen and accelerating \textit{N}_2 production.

However, an enhanced summer monsoon would also increase river runoff and the flux of particulates to the BoB. Riverine particulates ballast sinking organic material resulting in rapid sedimentation of labile organics through the OMZ, reducing their decomposition in OMZ waters\textsuperscript{6}. Thus, the main climate driver in the BoB, the summer monsoon, generates what appear to be opposing influences on the development of anoxia in the BoB OMZ waters. A test of summer monsoon intensity on \textit{N}_2 loss in the BoB could come from current climate change as some climate models suggest future increases in the intensity of the Asian summer monsoon\textsuperscript{31}.

Historical evidence indeed suggests a potential relationship between climate change and an active anaerobic nitrogen cycle in the BoB\textsuperscript{32}. Elevated sediment nitrogen isotope values are correlated with elevated concentrations of organic matter and organic nitrogen about 42,000 years ago. These results suggest that higher rates of organic matter productivity at that time enabled a nitrogen cycle with higher \textit{N} loss rates, although the driver of this relationship is unclear.

Overall, we demonstrate that the BoB is like the other well known OMZs with microbial populations supporting \textit{N}_2 production, although at low rates. The BoB OMZ also maintains widespread nanomolar oxygen concentrations that inhibit the stable accumulation of nitrite, a key substrate for \textit{N}-loss. If these last traces of oxygen were removed, allowing nitrite to accumulate, rates of \textit{N}_2 production would increase considerably. Thus, the BoB OMZ sits at a geochemical “tipping point” where any process removing the last of the oxygen, such as anthropogenic nutrient input or climate change, would make the BoB a major player in the marine nitrogen cycle.

Figure Captions

Figure 1. Station locations and oxygen data for the Bay of Bengal. Oxygen concentration profiles focus on the upper 500 m of the water column containing the oxygen minimum zone (OMZ). Black dots represent STOX oxygen data, while the blue line represents Seabird oxygen data, calibrated with the STOX data at the low oxygen levels. At Station 1 (a), nitrite concentrations are indicated by the red line (a distinct primary nitrite maximum in the oxic upper 100m, and a secondary nitrite maximum under nanomolar oxygen concentrations). Nitrite was not detected at any of the other stations.

Figure 2. Abundance of bacterial 16S rRNA and selected functional genes in the Bay of Bengal. Copy numbers were obtained with qPCR using primer sets as shown in Table S3. Shown are total copies of bacterial 16S rRNA (a), nitrite reductase genes attributed to denitrifiers (Denitrifier nirS; b) and to anammox bacteria (Scalindua, Sc nirS; c), thaumarchaeotal ammonia monooxygenase (Th amoA; d) and Nitrospira/Nitrospina nitrite oxidoreductase (nxrB; e). The dashed rectangle outlines the approximate depth interval where oxygen concentrations drop below 2.5 µM. Error bars represent the standard deviation. Note variability in x axes scales.

Figure 3. Depth profiles and regulation experiments of N transformations in the Bay of Bengal a) Process rate experiments showing rates of anammox and nitrate reduction to nitrite using $^{15}$N labeling experiments. Denitrification was below detection in these experiments: b) Experiments using $^{15}$N-labeled nitrite to explore the oxygen regulation of nitrogen transformations. The top panel shows the oxygen regulation of nitrite oxidation (note the use of both y axes), the middle panel shows the oxygen regulation of denitrification, while the bottom panel shows the oxygen regulation of anammox. Error bars represent the standard error.

Figure 4. Geochemical indicators of nitrogen cycling in the Bay of Bengal OMZ waters. Depth profiles of excess N$_2$ (calculated from N$_2$/Ar ratios; a), and the N deficit (b; calculated as $[NO_3^- + NO_2^-] - (N/P_{bw} * [PO_4^{3-}])$, with N/P$_{bw}$ being the average NO$_3^-$ + NO$_2^-$; PO$_4^{3-}$ ratio seen in bottom waters during this cruise, which was assigned a value of 14). The $\delta^{15}$N of nitrate, along with a depth profile of average nitrate concentrations (solid black line; grey shading shows upper and lower bounds) from all stations (c), and the $\delta^{18}$O of nitrate (d). The dashed rectangle outlines the approximate depth interval where oxygen concentrations drop below 2.5 µM.
Methods

Samples were collected at seven stations (Table S4) in the Bay of Bengal between the 24th of January and 3rd of February 2014 onboard the ORV Sagar Kanya. Seawater samples were collected using Niskin bottles (4x30 L and 8x5 L) on a rosette containing a Conductivity Temperature Depth (CTD) profiler (SBE 9/11 – SeaBird Electronics). The CTD was furthermore equipped with a SBE 43 oxygen sensor (see below) and WET Labs ECO-AFL/FL chlorophyll sensor. A complete array of samples, hydrographic, molecular, nutrients, geochemical and rate measurements were undertaken at stations 1, 4, and 5. At station 6, hydrographic, nutrient, geochemical and a reduced number of rate measurements were sampled for. Only hydrographic and a reduced number of rate measurements were undertaken at station 7 and, at stations 2 and 3 hydrographic profiles only.

In situ O₂ measurements

Concentrations of oxygen were measured in situ with two methods. In order to assess the possibility of true anoxia in BoB waters we used STOX (Switchable Trace amount OXygen) amperometric oxygen sensors mounted to a CTD frame. The signal from the STOX sensor was recorded on a custom-made Trace oxygen profiler (TOP)34, consisting of a 16-bit A/D converter (DT9818, Data translation) controlled by a single board computer (fit-PC2i, CompuLab) housed in a titanium cylinder. The amplification of the STOX sensor signal was performed by a custom-made amplifier and the operation of the sensor switching was controlled by a cyclic switch operating with a 40 s on/off cycle. Data was sampled at 60 s⁻¹, filtered using 1.5 s⁻¹ low-pass filter, smoothed using a 5 s moving average and finally down-sampled to 1 s⁻¹. The detection limit of the STOX sensors in the given configuration was estimated to be 7-12 nM based on three times the standard deviations of the noise recorded in the zero signal. Calibration and calculations were performed as described previously33, 35.

STOX measurements were performed at Stations 1,4,5,6 and 7. At Station 1, STOX measurements were only performed to a depth of 270 m, due to a software error. The STOX data were recorded during the up-cast (except at Station 1) and the majority of the data were recorded while the instrument was moving. Additionally, several recordings were performed while the instrument was kept at a given depth for 3-5 min. These data are not distinguishable from data recorded as the CTD moved. All STOX oxygen data are presented in Table S1.

We also measured oxygen with the SBE 43 polarographic oxygen sensor mounted on the CTD. The data from the CTD was sampled at 24 s⁻¹, low-pass filtered at 0.15 s⁻¹ and down sampled to 1 s⁻¹. Only data
from the up-cast was used, as typical for oxygen measurements in OMZs (e.g.\textsuperscript{35}), and casts were performed with a CTD speed of approximately 1 m s\textsuperscript{-1} below 100 m and 0.5 m s\textsuperscript{-1} above 100 m. The data from the SBE 43 and STOX were aligned using the pressure data recorded by both instruments.

When compared, the data from the SeaBird and STOX sensors showed excellent linearity (Figure S2), but with a positive offset on the order of 400 to 500 nM in the SeaBird oxygen reading. In principle we could have used this offset to calibrate the Seabird data to the STOX data, but when doing so, we found that the SeaBird sensor produced a large number of negative readings at the lowest oxygen levels. Since the STOX sensor clearly showed the persistence of oxygen in the OMZ, we elected instead to align the lowest readings on the SeaBird sensor with the readings from the same depth from the STOX sensor. This ensured that the Seabird readings were always positive values, and the offset ranged from 380 nM to 450 nM at the different sites.

**DNA sampling and methods**

Samples for molecular biological work were collected at Stations 1, 4, and 5 at water depths ranging from 10 m to 2300 m. Between 5 and 27 L of water per depth was filtered through a 3 \( \mu \)m pre-filter prior to a 0.22 \( \mu \)m Supor\textsuperscript{®} PES membrane disc filter (PALL) on which we collected material for DNA analysis. Each membrane was stored in 2.7 mL sucrose lysis buffer (SLB) at -20°C until DNA extraction.

**DNA extraction**

DNA was extracted after a modified version of the phenol:chloroform extraction\textsuperscript{36}. Membranes in 2.7 mL SLB were allowed to thaw at room temperature. After addition of 150 \( \mu \)L of lysozyme (20 mg/ml) tubes were incubated at 37 °C for 30 min under constant rotation. After this, 150 \( \mu \)L 20\% (w/v) sodium dodecyl sulfate and 150 \( \mu \)L of proteinase K (20 mg/ml) were added and tubes were incubated at 55 °C for 120 min under continuous mixing. Nucleic acids were extracted with 1 volume phenol:chloroform:isoamylalcohol (IAA) (25:24:1) followed by centrifugation at 2,500 relative centrifugal force (rcf) for 10 min. The remaining phenol was extracted by 1 volume chloroform:IAA (24:1) followed by a centrifugation at 2,500 rcf for 5 min. Genomic DNA was precipitated with 0.1 volume of 3 M sodium acetate and 2-3 volumes of 96\% ethanol, incubation at -20 °C for 8 hr. DNA was pelleted at 14,000 rcf for 45 min at 4 °C and washed with 70\% ice-cold ethanol and centrifuged at 14,000 rcf for 30 min at 4 °C. The DNA was air dried at RT and resuspended in 100 \( \mu \)L preheated TE
buffer (60 °C; pH 7.5). DNA concentrations, quality, and purity were checked spectrophotometrically (NanoDrop) and by the Quant-iT™ PicoGreen® dsDNA kit (Invitrogen).

qPCR

Copy numbers of 16S rRNA genes and functional genes were determined by qPCR using primer sets, concentrations, and specific conditions listed in Table S3. Each 20 µL reaction contained 10 µL SsoAdvanced™ SYPER® Green Supermix (Bio-Rad), 1-8 ng of template DNA and was adjusted to 20 µL final volume with nuclease-free water. Reactions were carried out in clear 96 Multiply® PCR plates (Sarstedt) and performed on a CFX Connect Real-Time System (Bio-Rad) running CFX Manager™ Software V3.0. General conditions were as follows: 98 ºC for 2 min followed by 40 cycles of 98 ºC for 5 s, listed annealing temperature for 15 s, 72 ºC for 15 s and a plate read. Finally, a melt curve from 65 ºC to 95 ºC held at each 0.5 ºC for 5 sec was performed to check the specificity of the reaction.

All reactions were run alongside standard curves of the corresponding gene ranging from $10^1$ to $10^7$ copies per µL. Mean PCR efficiencies for the standard curves are listed in Table S3 ($R^2$ values were all >0.99). Standards for each target gene were derived from clone libraries prepared from environmental samples with the same primers that were used for the qPCR.

Nutrients

Nitrate, nitrite and phosphate concentrations were determined following methods outlined in 37. The nitrogen deficit was calculated as $[\text{NO}_3^- + \text{NO}_2^-] - (N/P_{bw} \times [\text{PO}_4^{3-}])$, with $N/P_{bw}$ being the average $\text{NO}_3^- + \text{NO}_2^-$, $\text{PO}_4^{3-}$ ratio seen in bottom waters during this cruise, which was 14. Nutrient data is presented in Table S4. It is important to note here the weakness in using the N deficit in these waters. The various source waters, water masses, riverine input, and monsoonal rains are poorly constrained, and likely have varying N/P ratios, which could impact the N deficit calculation.

Excess N₂: Sampling and Analysis

Samples for high precision N₂/Ar measurements for the determination of biogenic N₂ were collected and analyzed following the protocol outlined in ref 38. Samples were collected bubble-free in 60mL serum bottles, preserved with 100 µL of saturated HgCl₂ and stored at ambient temperature until analysis. Analyses were carried out on a custom-made on-line gas extraction system coupled to a multicollector IRMS (GV Isoprime). Oxygen was removed during gas purification by a hot copper furnace to avoid artifacts associated with varying N₂/O₂. Calibration was achieved through reference gas injections
(N₂+Ar) and air equilibrated water standards of known temperature and salinity. To assess the contribution from biogenically produced N₂ an additional background correction was applied. This was done by subtracting values from waters uninfluenced by N loss processes. In our study, no stations outside of the low-oxygen region were sampled, so background data was taken from the WOCE 107N line.

Samples collected at depth (temperature 3 to 10 °C) showed unusually high excess N₂. Increases with depth may be expected due to bubble injection during water mass formation, but should have been accounted for within the background correction. Samples were analyzed within 4 months of collection, at which time the integrity of the excess N₂ measurements should not have been compromised based on sample longevity tests. However the longevity tests were conducted with storage at room temperature and not elevated and fluctuating temperatures as our samples likely experienced during transport. Storage effects will be highly dependent on the temperature difference between that observed in situ and that experienced during storage. As temperature in the open ocean has a clear monotonic distribution, we therefore also expect the residual excess N₂ as a result of storage to follow a similar distribution whereas a peak of excess N₂ in the shallower, warmer, low oxygen waters would suggest a biogenic signature from processes occurring in situ. Results are presented in Table S4.

Nitrate Isotopes

Samples for δ¹⁵N(NO₃) (δ¹⁵N (‰ vs. atmospheric N₂) = [(¹⁵N/¹⁴N)NO₃/(¹⁵N/¹⁴N)N₂-1] x 1000) and δ¹⁸O(NO₃) (δ¹⁸O (‰ vs. VSMOW) = [(¹⁸O/¹⁶O)NO₃/(¹⁸O/¹⁶O)VSMOW-1] x 1000) were collected in 60mL acid-washed HDPE bottles and stored frozen until analysis. Samples were analyzed by cadmium reduction to NO₂⁻ followed by reduction to N₂O with azide. Pre-existing NO₂⁻ was removed by adding sulfamic acid prior to cadmium reduction. International standards IAEA-N3, USGS-34 and USGS-35 were used for calibration. Reproducibility was 0.3 and 0.5 ‰ for δ¹⁵N(NO₃) and δ¹⁸O(NO₃) respectively. Results are presented in Table S4.

Process rate experiments

Rates of microbial nitrogen turnover were determined using ¹⁵N labeled substrates. Experiments were carried out at six depths at stations 1, 4 and 5 and at three depths at stations 6 and 7, following the methods outlined in refs. For each incubation, a 250 mL serum bottle was filled directly from the Niskin bottle and overflowed for at least three volume changes, then immediately capped with a butyl rubber stopper and crimped with an aluminum cap. Bottles were stored in the dark at in situ temperature.
until all depths were collected. After this, bottles were purged with helium for 15 min and amended with

\(^{15}\text{N}\)-labeled substrates during the purging. Four amendments were made: 1) 5 \(\mu\text{M}^{15}\text{NH}_4^+\), 2) 5 \(\mu\text{M}^{15}\text{NO}_2^- + 5 \mu\text{M}^{14}\text{NH}_4^+\), 3) 5 \(\mu\text{M}^{14}\text{NO}_2^- + 5 \mu\text{M}^{15}\text{NH}_4^+\) and 4) 25 \(\mu\text{M}^{15}\text{NO}_3^-\) (only amendments 2 and 3 were carried out at stations 6 and 7). \(^{15}\text{N}\)-amended samples were transferred into 12 mL exetainers (LabCo, UK), and capped with helium degassed caps to avoid oxygen contamination\(^{48}\). Exetainers were incubated in the dark at \textit{in situ} temperature. At each time point (approximately 0, 3, 6, 12 and 24 hr), microbial activity was terminated in a single exetainer by the addition of 100 \(\mu\text{L}\) of saturated mercuric chloride solution. It is worthwhile to note that although the incubation approach used here was originally intended to yield anoxic conditions, the introduction of highly sensitive oxygen sensors have revealed that slight oxygen contamination is essentially unavoidable\(^{49,50}\).

The production of \(^{14}\text{N}^{15}\text{N}\) and \(^{15}\text{N}^{15}\text{N}\) was determined on a gas-chromatography isotope ratio mass spectrometer (GC-IRMS; VG Optima, Manchester, UK). The production of nitrite was determined from samples amended with \(^{15}\text{NO}_3^-\) according to ref\(^{47}\) with conversion to \(\text{N}_2\) and determination of \(^{14}\text{N}^{15}\text{N}\) by GC-IRMS (customized TraceGas coupled to a multicollector IsoPrime100, Manchester, UK). Rates for all processes were evaluated from the slope of the linear regression of \(^{14}\text{N}^{15}\text{N}\) and/or \(^{15}\text{N}^{15}\text{N}\) with time, correcting for the \(^{15}\text{N}\) labeling percentages of the initial substrate pool. Rates of \(\text{N}_2\) production by anammox and denitrification were calculated according to the equations in ref\(^{51}\). T-tests were applied in all cases to determine whether rates were significantly different from zero (\(p < 0.05\)). Detection limits varied from experiment to experiment and were estimated from the median of the standard error of the slope, multiplied by the t value for \(p = 0.05\). Thus, the median detection limits for anammox were 1.3 and 2.2 nM N d\(^{-1}\) for \(^{15}\text{NH}_4^+\) and \(^{15}\text{NO}_2^-\) incubations, 2.7 nM N d\(^{-1}\) for denitrification (\(^{15}\text{NO}_2^-\) incubation) and 3.0 nM N d\(^{-1}\) for nitrate reduction (\(^{15}\text{NO}_3^-\) incubation; anammox and denitrification rates were all non-significant with \(^{15}\text{NO}_3^-\) amendments).

**Oxygen Regulation Experiments**

Water for oxygen regulation experiments was sampled immediately after the Niskin bottles arrived on deck and transferred to a 20 L glass bottle. The bottle was overflowed (at least two volume equivalents) and sealed without bubbles using deoxygenated butyl rubber stoppers\(^{48}\), then stored in the dark at \textit{in situ} temperature until the experiment began. The bottle was spiked with \(^{15}\text{NO}_2^-\) to a final concentration of 5 \(\mu\text{M}\) and then degassed with helium (~ 1 hr). At this point, the water was dispensed into custom-modified Schott Duran glass bottles (1160 mL) as described in ref\(^{52}\). An additional modification was the
placement of a third glass port on the bottle, which held a 100 mL glass reservoir filled with sample water, that was continually degassed with helium for the duration of the experiment. During the incubations the bottles were continuously stirred\textsuperscript{52}, kept in the dark, and submersed in a water bath to maintain \textit{in situ} temperature. Oxygen additions were made by injecting known volumes of air-saturated seawater. In this setup, oxygen was monitored throughout the incubations using a highly sensitive optical trace oxygen optode and readout device\textsuperscript{50}, mounted on the side of the bottle. Sensors were individually calibrated after each experiment, with zero point calibrations using a 0.1% w/v sodium-dithionite solution.

Time-series sampling was undertaken at 0, 4, 8, 12 and 16 hr, by inserting a long needle down the pressure compensation tube, opening the reservoir and withdrawing 10mL of sample. Sample was injected into 6 mL exetainers (LabCo, UK), pre-spiked with 50 µL 50% w/v ZnCl\textsubscript{2}. Analysis of \textsuperscript{14}N\textsuperscript{15}N and \textsuperscript{15}N\textsuperscript{15}N for N\textsubscript{2} production rates were performed on a gas chromatography isotope ratio mass spectrometer as in \textsuperscript{53}. Anammox and denitrification rates were determined using the equations presented in ref\textsuperscript{51}.

Nitrite oxidation was determined from the production of \textsuperscript{15}NO\textsubscript{3}-. After the removal of residual \textsuperscript{15}NO\textsubscript{2} with sulfamic acid, \textsuperscript{15}NO\textsubscript{3} was converted to \textsuperscript{15}NO\textsubscript{2} by cadmium reduction and then to N\textsubscript{2} with sulfamic acid\textsuperscript{42,47}. Process rates were calculated from the linear regression of \textsuperscript{14}N\textsuperscript{15}N and/or \textsuperscript{15}N\textsuperscript{15}N as a function of time. T-tests were applied in all cases to determine whether rates were significantly different from zero (p < 0.05). Detection limits for the oxygen regulation experiments were estimated from the median of the standard error of the slope, multiplied by the t value for p = 0.05. Detection limits vary from experiment to experiment, but median detection limits were 0.9 nM N d\textsuperscript{-1} for anammox in \textsuperscript{15}NO\textsubscript{2} incubations, 0.4 nM N d\textsuperscript{-1} for denitrification and 6.3 nM N d\textsuperscript{-1} for nitrite oxidation. Data from these experiments are shown in Table S2.
