Abstract

The past variability of the South Asian Monsoon is mostly known from records of wind strength over the Arabian Sea while high-resolution paleorecords from regions of strong monsoon precipitation are still lacking. Here, we present records of past monsoon variability obtained from sediment core SK 168/GC-1, which was collected at the Alcock Seamount complex in the Andaman Sea. We utilize the ecological habitats of different planktic foraminiferal species to reconstruct freshwater-induced stratification based on paired Mg/Ca and δ¹⁸O analyses and to estimate seawater δ¹⁸O (δ¹⁸Osw). The difference between surface and thermocline temperatures (ΔT) and δ¹⁸Osw (Δδ¹⁸Osw) is used to investigate changes in upper ocean stratification. Additionally, Ba/Ca in G. sacculifer testsis used as a direct proxy for riverine runoff and sea surface salinity (SSS) changes related to monsoon precipitation on land. Our Δδ¹⁸Osw time series reveals that upper ocean salinity stratification did not change significantly throughout the last glacial suggesting little influence of NH insolation changes. The strongest increase in temperature gradients between the mixed layer and the thermocline is recorded for the mid-MIS 3 (~37 kyrs) and indicate the presence of a significantly shallower thermocline. In line with previous work, the δ¹⁸Osw and Ba/Ca records demonstrate that monsoon climate during the LGM was characterized by a significantly weaker southwest monsoon circulation and strongly reduced runoff. Based on our data the South Asian Summer Monsoon (SAM) over the Irrawaddyy strengthened gradually after the LGM beginning at ~18 ka. This is some 3 kyrs before an increase of the Ba/Ca record from the Arabian Sea and indicates that South Asian Monsoon climate dynamics are more complex than the simple N-S displacement of the ITCZ as generally described for other regions. Minimum δ¹⁸Osw values recorded during the mid-Holocene are in phase with Ba/Ca marking the wettest period during the past ~54 kyrs, which is consistent with model simulations.
1. Introduction

The South Asian Summer Monsoon (SAM) is a dominant feature of the global monsoon circulation that directly affects the livelihood of over a billion people residing in the region. The SAM is part of the large scale Asian monsoon system and is primarily driven by seasonal changes in land-sea thermal contrast and the annual cycle of the angle of the solar zenith (Meehl, 1994; Trenberth et al., 2000; Wang and Ding, 2008; Webster et al., 1998). The onset of the SAM during May and June is concurrent with the reversal of meridional temperature gradients in the upper troposphere over the Tibetan Plateau and regions to the south (Li and Yanai, 1996; Meehl, 1994; Wu and Zhang, 1998; Yanai et al., 1992). This reversal is the result of differential seasonal heating of the continent and surrounding oceans, which generates a strong pressure gradient leading to large-scale shifts in the position of the Intertropical Convergence Zone (ITCZ) and the initiation of the low level cross equatorial southwest monsoon wind circulation. Consequently, a landward tropospheric cyclonic flow coupled with a persistent deep atmospheric convection causes convergence of moisture fluxes on the Indian subcontinent (Chen, 2003; Lau et al., 2000; Randel and Park, 2006), with the Bay of Bengal/Andaman Sea and surrounding catchments being major moisture sinks (Yihui et al., 2004).

The SAM has exhibited pronounced variability over a wide range of time scales. The roles of the El Niño Southern Oscillation (ENSO) (Pant and Parthasarathy, 1981; Rasmusson and Carpenter, 1983; Webster and Yang, 1992) and Eurasian snow cover (Dickson, 1984; Hahn and Shukla, 1976; Kumar et al., 1999) on the interannual fluctuations of the SAM have been widely documented. Other studies have highlighted the combined effects of changes in the North Atlantic Oscillation (NAO) and in the Southern Oscillation (SO) on seasonal monsoon patterns (Kakade and Dugam, 2000; Viswambharan and Mohanakumar, 2014). Decadal to centennial scale variations in monsoon precipitation have been in phase with temperature fluctuations in northern high latitudes (Fleitmann et al., 2003). Monsoonal changes on millennial to longer time-scales were principally driven by orbitally-induced changes in solar insolation prompting shifts in the mean position of the ITCZ (Fleitmann et al., 2007; Overpeck et al., 1996; Sirocko et al., 1993; Wang et al., 2005).

The past variability of the SAM has mostly been inferred from records of wind strength and the associated intensity of upwelling in the Arabian Sea (Caley et al., 2011; Clemens et al., 1991; Clemens et al., 1996; Clemens et al., 2008; Schulz et al., 1998; Ziegler et al., 2010). Several studies from the Arabian Sea have documented that the intensity of the SAM was characterised by millennial scale variations superimposed on long term glacial-interglacial variability (Agnihotri et al., 2002; Overpeck et al., 1996; Sarkar et al., 1990; Schulz et al., 1998; von Rad et al., 1999). Other studies, mainly based on upwelling indices such as foraminifera (% Globigerina bulloides) and
changes of eolian inputs, have argued that the strength and timing of the monsoon winds are primarily linked to the obliquity and precession of the Earth’s orbit rather than long term glacial-interglacial variability (Clemens et al., 1991; Clemens et al., 1996; Clemens et al., 2010; Clemens et al., 2008). However, interpretations relying on the wind based proxies have been challenged as monsoonal precipitation over the subcontinent depends more on the moisture content of the interhemispheric monsoon winds and their transport pathways rather than wind strength (Ruddiman, 1997; Sarkar et al., 2000). It is also clear that the application of the occurrence of microfossils as upwelling indicators is sensitive to many environmental factors, some of which are possibly unrelated to the monsoon (Clemens and Prell, 2003; Ziegler et al., 2010). As a result, considerable discrepancies with regard to the past variability of the SAM recorded by proxies from different regions remain unresolved. High-resolution proxy records from regions with strong monsoonal rainfall influence are therefore required to examine past changes of SAM intensity. In this regard, the Andaman Sea and the Bay of Bengal, where both monsoonal precipitation over the ocean and the continental runoff can be assessed, offer a unique prospect for understanding the past variability of the SAM. Despite this, relatively few studies have attempted to reconstruct SAM variability using proxy records of salinity in the Bay of Bengal (Govil and Naidu, 2011; Kudrass et al., 2001; Rashid et al., 2011) and in the Andaman Sea (Rashid et al., 2007). Kudrass et al., (2001) published a record of the SAM variability and sea surface salinity changes for the last 80kyrs by combining $\delta^{18}O$ signatures of Globigerinoides ruber (G. ruber) and alkenone based temperature estimates. Similarly, paired $\delta^{18}O$ and Mg/Ca signals of planktonic foraminifera species were used to reconstruct seawater $\delta^{18}O$ ($\delta^{18}O_{sw}$) and to infer sea surface salinity (SSS) trends during the Last Glacial Maximum (LGM) and the deglaciation in the Bay of Bengal (Govil and Divakar Naidu, 2011; Rashid et al., 2011) and the Andaman Sea (Rashid et al., 2007). More recently, however, a growing number of studies have used Ba/Ca ratios of planktic foraminiferal tests to infer past river water discharge and estimate SSS changes (e.g. Luduc et al., 2013; Weldeab et al., 2007; Weldeab et al., 2014). This is based on the fact that riverine runoff is enriched in dissolved Ba relative to sea water (Bahr et al., 2013; Hall and Chan, 2004; Schmidt and Lynch-Stieglitz, 2011) and Ba incorporation into foraminiferal shells occurs in direct proportion to the corresponding seawater Ba concentration (Hönisch et al., 2011; Lea and Spero, 1992; Lea and Spero, 1994).

Here, we utilise the depth habitat preferences of different foraminifera species to investigate the freshwater-induced stratification in the Andaman Sea with paired Mg/Ca and $\delta^{18}O$ measurements on Globigerinoides sacculifer (G. sacculifer) and Neogloboquadrina dutertrei (N. dutertrei). These recorders of mixed layer and thermocline temperature ($\text{SST}_{\text{Mg/Ca}}$ and $\text{TT}_{\text{Mg/Ca}}$) and $\delta^{18}O$, respectively, are used to construct $\delta^{18}O_{sw}$ records, which approximate salinity at the respective water depth. The
difference in surface and thermocline temperatures ($\Delta T$) and $\delta^{18}$O$_{sw}$ ($\Delta\delta^{18}$O$_{sw}$) are used to infer changes in upper ocean stratification. Ba/Ca ratios of *G. sacculifer* tests are generated to assess changes in riverine runoff and provide the first such record for the Andaman Sea spanning the last 54 kyr.

2. Materials and methods

2.1. Oceanographic Setting

The Andaman Sea is a marginal sea located in the northeastern corner of the Indian Ocean between the Malay Peninsula and the Andaman and Nicobar Islands. With a maximum water depth of 4200m, it is connected with the Bay of Bengal and the Australasian Mediterranean Sea through several channels between the chain of the Andaman Islands and the Malacca Strait, respectively. The distribution of temperature and salinity with depth in the Andaman Sea is similar to that of the Bay of Bengal down to a depth of about 1000 m (Sarma and Narvekar, 2001). The Andaman Sea experiences strong seasonal variations in salinity due to abundant freshwater discharge from the Irrawaddy and Salween Rivers during the summer monsoon (Chapman et al., 2015). Distinct differences in deep sea temperature and salinity structure in the Andaman Sea are caused by the enclosed nature of the Andaman Basin and presence of several sills between the islands inhibiting deep water exchange between these two regions (Ramesh Babu and Sastry, 1976; Rao and Jayaraman, 1968; Sengupta et al., 1981). The Ganges–Meghna–Brahmaputra and Irrawaddy-Salween river systems on average discharge 1350 and 1000 km$^3$ of freshwater annually to the Bay of Bengal and the Andaman Sea, respectively (Sengupta et al., 2006) thereby influencing mixed layer depth and salinity. In the Irrawaddy catchment, monsoon rains increase discharge from an average of ~12 km$^3$/month during the winter and up to ~89 km$^3$/month in the summer (Chapman et al., 2015). In the Andaman Sea, mean summer surface water salinity ranges between 28 and 33‰ (Levitus et al., 2013). The average near-surface temperature is 29°C and is nearly homogenous in the mixed layer down to a depth of 50m, below which stratification of the water masses restricts vertical mixing (Sarma and Narvekar, 2001; Uddin et al., 2014). The top of the thermocline varies seasonally between ~40 and ~60 meters but is generally situated at a depth of ~50m (Riser et al., 2008).

2.2. Core location and sample preparation

Sediment core SK 168/GC-1 (Lat. 11°42.463′ N; Long. 94°29.606′ E, water depth: 2064 m, core length: 4.20 m) was collected during the 168th cruise of ORV Sagar Kanya from the Alcock Seamount Complex in the Andaman Sea. A late Quaternary record of pteropod abundance and the $\delta^{18}$O record from the surface dwelling plankticforaminiferal species *G. ruber* has previously been published (Sijinkumar et al., 2010). The age model from (Sijinkumar et al., 2010) was constructed
with 5 Accelerator Mass Spectrometer (AMS) $^{14}$C dates of planktic foraminiferal tests (mixed *G. ruber* and *G. sacculifer*). The AMS $^{14}$C ages were uniformly corrected for a 460 year reservoir age following Butzin et al. (2005). The age model was further refined by correlating the oxygen isotope values of *G. ruber* with the stacked reference oxygen isotope curve of Martinson et al. (1987) and constant sedimentation rates were assumed between age tie points. The average sedimentation rate for the core is 7.79 cm/kyr with variations between ~3.65 and ~10.20 cm/kyr during the MIS3/MIS 2 and the Pleistocene-Holocene transitions respectively (Sijinkumar et al., 2010). This provides an average temporal resolution of ~700 yrs for the upper 2 m of the core spanning the Holocene to the MIS3/MIS2 transition. Below this section the temporal resolution is ~1.3 kyrs. The accuracy of this age model has been confirmed by comparison to the recently published benthic foraminifera $\delta^{18}$O data for ODP 758 (Bolton et al., 2013) (Supplement Fig 1) and is in line with a new benthic foraminifera $\delta^{18}$O data from core SK 168/GC-1 discussed in detail in a separate publication (Sijinkumar et al., 2016, in press QSR). Thus, the published age model for the core is employed without any modifications.

Foraminifera samples from the core section were collected, and analyzed every 5 cm down to 2 m and every 10 cm for the remaining 2.2 m of the core. The abundance of foraminiferal specimens was limited in these clay rich sediments, particularly for *G. sacculifer*, and 15-20 specimens available per sample and 10 specimens per sample in some 4 samples were considered enough to obtain a representative geochemical signature, although ideally this would be more (Laepple and Huybers, 2013). For trace element analysis a constant and narrow size fraction of foraminifera is desired to avoid possible size dependent biases (e.g. Elderfield et al., 2002; Ni et al., 2007). Specimens of *G. sacculifer* and *N. dutertrei* were selected from the 315-400 μm size fraction and gently cracked between glass slides before being mixed and split for trace metal and stable isotopic analyses. For trace metal analysis the cracked sample was cleaned following a full reductive cleaning method (Boyle, 1981). Samples were initially repeatedly rinsed with sonication in distilled water (18.2 mΩ) and then ethanol (analytical grade) to ensure clay removal. Samples were then inspected under a binocular microscope to ensure they were free of obvious sediment contamination. Subsequently, samples were treated with ammonium citrate/hydrazine solution at 82°C for 30 mins and sample racks were placed in the ultrasonic bath for one minute every 10 mins to maintain contact between reagents and sample. Samples were rinsed multiple times with distilled water before being transferred to new acid leached vials. Samples were then treated with oxidizing NaOH/H$_2$O$_2$ solution at 82°C for 20 mins to remove organic matter. After three more rinses with distilled water, a weak acid leach with 100 μL 0.001 M HNO$_3$ was applied and followed by two rinses with distilled water. Samples were dissolved in 0.075 M nitric acid (HNO$_3$) (500 μL) assisted by sonication for 25 mins.
Finally samples were centrifuged for 4 mins at 13400 rpm and 400 μL of supernatant was transferred to new acid leached vials and diluted for measurement.

2.3. Foraminiferal isotopic and elemental analysis

The $\delta^{18}$O measurements were performed using a MAT 253 mass spectrometer coupled with a Kiel IV Carbonate device (Thermo Scientific). Results were referenced to the NBS19 standard and are given on the VPDB scale. The estimated analytical error for $\delta^{18}$O measurements was 0.05‰ (1σ) based on repeated measurements of an in house standard (SHK Bremen). Seawater $\delta^{18}$O ($\delta^{18}$O$_{sw}$) was calculated using the calibration equation of Bemis et al. (1998) and was corrected for global ice volume following Waelbroeck et al. (2002). $\delta^{18}$O$_{sw}$ values were converted to Vienna Standard Mean Ocean Water (VSMOW) by adding 0.27‰ to $\delta^{18}$O$_{sw}$. Uncertainties in $\delta^{18}$O$_{sw}$ are estimated by propagating the errors from the G. sacculifer and N. dutertrei $\delta^{18}$O and Mg/Ca measurements following (Bevington and Robinson, 2003) and are on average 0.4‰.

Element/Ca ratios were measured with an Agilent 7500cx ICP-MS. In a first step Ca concentrations were measured using Sc as an internal standard and these data were used to dilute the samples to 10ppm Ca for elemental analysis. Element/Ca ratios were calculated using intensity ratios (Rosenthal et al., 1999) that were calibrated using standards produced gravimetrically from single element solutions. The average Mg/Ca of carbonate reference material ECRM 752-1 (Greaves et al., 2008) measured during the course of the study was $3.83 \pm 0.06$ mmol/mol ($n=12$, 2σ). Uncertainties in SST reconstructions are estimated by propagating the errors introduced by Mg/Ca measurements and the Mg/Ca-Temperature calibration equation and are on average ±1 °C. SST$_{Mg/Ca}$ and TT$_{Mg/Ca}$ estimated from Mg/Ca data for G. sacculifer (G. ruber) and N. dutertrei are based on a calibration equation obtained from North Atlantic given for the species (Anand et al., 2003). SSS was estimated from Ba/Ca ratios of G. sacculifer using a function based on sea water Ba (Ba$_{sw}$) concentrations and salinity data obtained from the Bay of Bengal (Singh et al., 2013) and a Ba/Ca$_{sw}$–foraminiferal calcite partition coefficient (DBa) of 0.19 (Lea and Boyle, 1991) (See supplement Fig 2).

Clay minerals are major sources of contamination for Mg/Ca analysis of foraminifera shells (Barker et al., 2003). To exclude such biases, aluminum (Al) and iron (Fe) concentrations were carefully monitored to identify the presence of clay contaminants. For the data set presented here there is no systematic relationship between Al/Ca (or Fe/Ca) and Mg/Ca ratios indicating the absence of clay contamination. However, Al/Ca values in 8 samples were higher than in all other samples and these data were excluded from further interpretations. In a similar manner, Ba/Ca values were compared with La/Ca values to check for barite contamination based on the idea that La is removed from sea water by barite formation (Garcia-Solsona et al., 2014). Ba/Ca ratios do not show a linear
relationship with La/Ca ratios. However, we assume that significantly elevated Ba/Ca values (> 3 µmol/mol) in 9 samples are the result of barite contamination and were excluded from further interpretation.

3. Results

3.1 Sea Surface Temperatures and $\delta^{18}O$

Mg/Ca based estimates of SST ($SST_{Mg/Ca}$) and thermocline temperatures ($TT_{Mg/Ca}$) are shown in Fig. 2a. The SSTs range from 29 °C to 24 °C whereas the thermocline temperatures range from 24.5 °C to 19 °C. Coldest SSTs are observed during MIS3 centered at 33-37 kyr and during the last glacial maximum (LGM). The average LGM SST of 25.8 °C in the Andaman Sea are similar to the late Holocene (defined here as the average of the top 15cm of the core representing the last ~2.7 kyrs) with in the margin of error. Thermocline temperatures also do not show a distinct trend during these two time intervals. Additional $G. ruber$ measurements obtained from late Holocene and LGM samples reveal a similar SST cooling in the range of ~1.0 -1.5°C (Fig. 2a) and indicate no significant difference between the records of the two species (paired-samples t-test, p<0.01). Although its difficult to distinguish such small changes from the inherent noise in the records, the deglacial warming pattern appears to have two warming steps from the onset of the last glacial termination during Heinrich Stadal 1 (HS1), (~18 -15 kyr) and to the transition from Bolling/Allerod (B/A) (~15-12.9 kyr) and Younger Dryas (YD) (~12.9 – 11.7 kyr) (Fig. 2a). The start of deglacial warming in the Andaman Sea is hard to pinpoint but peak mixed layer temperatures ~28°C are reached at the onset of the B/A. SST values gradually cooled to ~26°C during the Younger Dryas (YD). After the YD values increase to a mid-Holocene maximum of ~29°C before decreasing and remaining relatively constant at ~26°C through the late Holocene.

$G. sacculifer$ and $N. dutertrei$ $\delta^{18}O$ values generally show synchronous patterns with lighter values during the mid-Holocene (~7-4 kyr) and MIS3 (~27 -54 kyr) compared to the LGM (~23-19 kyr) (Fig 2b). $G. sacculifer$ $\delta^{18}O$ values during MIS3 ranged from -1.7 to -0.5‰ and varied synchronously with the $\delta^{18}O$ values of $N. dutertrei$. Mean $\delta^{18}O$ values of $G. sacculifer$ during the LGM progressively increased from -0.6‰ to -0.2‰ at around~19 kyr. The transition from the late glacial is marked by abrupt changes in $\delta^{18}O$ during the onset of the HS1 and the B/A. The transition from the B/A to the YD is marked by a 0.5 % increase in $\delta^{18}O$ values centered at ~12 kyr. Holocene $\delta^{18}O$ values gradually decreased and reached -2.8 % for $G. sacculifer$ and show a ~2% difference between the late glacial and mid-Holocene values. Late Holocene $\delta^{18}O$ values remained relatively constant and ranged between -2.5 and -2.7 ‰.
3.2 Ba/Ca ratios and Seawater $\delta^{18}$O

Ba/Ca and $\delta^{18}$O$_{SW}$ records of Core SK 168 reveal distinct changes in monsoon precipitation above the Irrawaddy catchment during the last ~54 kyrs (Fig 2c and 3e). Peaks in Ba/Ca and surface $G.\ sacculifer$$\delta^{18}$O ($\delta^{18}$O$_{sw}$) values are observed during the early part of the MIS3 and at the MIS3/2 transition centered at ~50 kyrs and ~35 kyrs, respectively. Ba/Ca gradually decreased from ~1.7 $\mu$mol/mol during the MIS3/2 transition to ~1 $\mu$mol/mol during the LGM which is equivalent to an SSS change from ~30 to 33‰. Minimum Ba/Ca values (0.86 $\mu$mol/mol) were recorded at ~19 ka. The deglacial transition is marked by a relatively abrupt decrease in $\delta^{18}$O$_{sw}$ values during the onset of HS1 and a gradual increase in Ba/Ca and $\delta^{18}$O$_{SW}$ values during the B/A. Ba/Ca values gradually increased from the LGM to the mid-Holocene reaching a maximum of 2.6 $\mu$mol/mol corresponding to a salinity minimum of ~27‰. Peak $\delta^{18}$O$_{sw}$ values during the mid-Holocene centered around ~5 kyrs were in phase with Ba/Ca peaks. Ba/Ca values during the late Holocene attained an average value of 1.7 $\mu$mol/mol corresponding to an SSS estimate of ~30‰. This is in agreement with modern summer SSS values in this region of the Andaman Sea that range between 28 and 33‰ (Levitus et al., 2013).

3.3 Vertical Temperature and $\delta^{18}$O$_{sw}$ ($\Delta\delta^{18}$O$_{sw}$) gradients

Changes in vertical temperature and $\delta^{18}$O$_{sw}$ gradients between the $G.\ sacculifer$ and $N.\ dutertrei$ ($\Delta\delta^{18}$O$_{sw}$) are considered a measure of the density gradient between the mixed layer and thermocline and are interpreted as a proxy for upper ocean stratification. The evolution of the $\Delta\delta^{18}$O$_{sw}$ and the temperature gradient between the mixed layer and the thermocline are shown in Fig 3b and c. The difference in measured $\delta^{18}$O$_{sw}$ between the two species ($\Delta\delta^{18}$O$_{sw}$) is on average 0.43 ‰ and ranges between -0.6 and 1.5 ‰, although the uncertainties associated with these calculations are ±0.4‰. The strongest increase in $\Delta\delta^{18}$O$_{sw}$ values is observed during the deglacial transition centered around the B/A. The temperature gradient between the mixed layer and the thermocline ranged between 1.7 and 10°C with large gradients between 38 -36 kyrs, the deglacial transition, and the mid-Holocene. The temperature gradient during the mid-Holocene was on average ~7.5°C while upper ocean density stratification remained fairly constant.

4. Discussion

4.1 Upper Ocean Stratification and monsoon intensity during the last glaciation

Given that the effect of global ice volume is cancelled out, the $\Delta\delta^{18}$O$_{sw}$ gradient between mixed layer and thermocline dwelling planktic foraminifera, a proxy for upper ocean stratification, is a function of local changes in $\delta^{18}$O$_{sw}$ of seawater and temperature. The application of the $\Delta\delta^{18}$O$_{sw}$
gradient to infer changes in surface water stratification is dependent on the differential depth habitats of the studied foraminiferal species. Mixed layer dweller *G. sacculifer* has been observed to live and calcify with in the upper 60 m of the water column (Fairbanks et al., 1982; Fairbanks et al., 1980), while *N. dutertrei* is generally most abundant in the thermocline (60-150 m) (Curry et al., 1983; Fairbanks et al., 1982). A sediment trap study conducted along a N-S transect in the Bay of Bengal (Fig 1) suggests that the abundance of mixed layer dwelling planktic foraminifera *G. sacculifer* does not change significantly with the seasons (Guptha et al., 1997). Thermocline dwelling *N. dutertrei* is also present throughout the year and exhibits a broad peak in abundance during the initiation of the summer monsoon, directly related to the low surface salinities associated with the monsoon (Cullen, 1981; Guptha et al., 1997). Thus, seasonal biases are most likely minimal in these species and observed long-term changes in $\delta^{18}\text{O}_{sw}$ largely reflect ‘year-round’ surface and thermocline conditions. However, the assumption that the optimum living depth of a given species in the past has remained similar to modern day observations may not always be the case (Field, 2004; Rohling et al., 2004).

We interpret changes in the upper ocean stratification as a consequence of thermocline depth changes driven by strong wind-induced mixing and monsoon precipitation driven upper ocean freshening, and vertical heat flux (Fig. 4). Thus, a larger $\Delta\delta^{18}\text{O}_{sw}$ gradient implies a shallower thermocline and a stronger vertical temperature gradient ($\Delta T$), while a small $\Delta\delta^{18}\text{O}_{sw}$ gradient indicates the presence of a deeper thermocline with relatively weak $\Delta T$ (Ravelo and Shackleton, 1995; Steinke et al., 2010; Steph et al., 2009). The strongest increase in temperature gradients between the mixed layer and the thermocline is recorded for the mid-MIS 3 (~37 kyrs) and indicate the presence of a significantly shallower thermocline. However, our $\Delta\delta^{18}\text{O}_{sw}$ time series reveals that upper ocean stratification did not change significantly during the glaciation and indicate broad decoupling between stratification of the upper ocean and NH insolation as well as monsoonal changes. This indicates that the relationship between upper ocean stratification and monsoon intensity changes in the paleorecord is more intricate than a unidirectional monsoonal forcing associated response invoked for present day stratification.

The climate in the SAM region has generally been described as cool and dry during the LGM (e.g. Cullen et al., 1981; Kudrass et al., 2001), which is supported by our higher salinity estimates for the Andaman Sea (~33‰). The physical mechanism often invoked to explain this weak SAM during the LGM is increased snow accumulation on the Tibetan Plateau causing shifts in the mean position of the ITCZ (Kudrass et al., 2001; Overpeck et al., 1996; Sirocko et al., 1996). The northeast winter monsoon circulation likely remained strong during the LGM with prevailing high-pressure cells in
the Tibetan plateau (Tibet High) in line with lower temperatures reported for the Tibetan Plateau (Shi, 2002) and Himalaya (Mark et al., 2005) weakening the meridional thermal land–sea contrast. Thus part of the weakening in SAM rainfall can be explained by an increased influence of dry continental airmasses entrained by the winter monsoon. Results from phases 2 and 3 of the Paleoclimate Modeling Inter-comparison Project (PMIP2 and 3) show that SAM precipitation was reduced in all models in the LGM experiments by as much as 1.7 mm/day due to changes in NH ice sheets extent (hence a strengthened Tibetan High) and atmospheric CO₂ concentration conditions (Braconnot et al., 2007). Modern meteorological data also support this interpretation and show that an increase of snow cover on the Tibetan Plateau strengthening the high pressure cell in winter leads to a weakened Tibetan Low and a weaker summer monsoon in the following year (Fang et al., 1999 and references therein).

4.2. The deglacial transition

The last deglaciation was punctuated by periods of Northern Hemisphere warming (B/A) and cooling (HS 1 and YD). Previous studies from the Bay of Bengal and the Arabian Sea indicate synchronous regional changes in deglacial warming and monsoon intensity remotely coupled to Greenland air temperature (Kudrass et al., 2001; Rashid et al., 2007; Schulz et al., 1998). Lighter δ¹⁸O values in mixed layer dwelling planktic G. sacculifer marking the last deglaciation lag the changes of the surface dwelling planktic foraminifera (G. ruber) by ~2 kyrs (Fig 5). This was also observed at ODP Site 758 in the southern Bay of Bengal (Bolton et al., 2013), and implies the slow propagation of salinity and temperature changes from surface to depth or a seasonal bias in one of the species. Upper ocean stratification around the B/A appears to have weakened rapidly. Deglacial Ba/Ca and δ¹⁸Osw trends are broadly synchronous and indicate a gradual monsoon strengthening with the exception of the HS1. G. sacculifer δ¹⁸Osw values indicate abrupt mixed layer freshening during HS1 consistent with other studies from the Arabian Sea that reported major intensification of the southwest monsoon around 15.5 ka (e.g. Naqvi and Fairbanks, 1996, Kessarkar et al., 2013). This is in contrast to the predominantly weak east Asian monsoon inferred for the Chinese speleothem records during HS1 (e.g. Wang et al., 2001). However, the gradual SAM strengthening observed in river runoff into the Andaman Sea began ~18 kyrs, leading Ba/Ca increases in the Arabian Sea around the B/A (Saraswat et al., 2013) by ~2-3kyrs (Fig 6). Together these data demonstrate SAM climate dynamics are more complex than the simple N-S displacement of the ITCZ following insolation changes as described for other regions (e.g. Overpeck, et al., 1996). The SAM appears to be strongly influenced by regional scale boundary conditions altering atmospheric convection as
evident from Holocene model simulations (PMIP3, Barconnot et al., 2012; Fig 7a and b) highlighting the importance of obtaining more SST records for this region.

4.3. The Holocene

Upper ocean stratification changes during the Holocene are marked by a gradual increase in temperature gradient and shoaling of the thermocline from early to mid-Holocene in response to increased heating of the mixed layer. This is indicated by a sharp $\Delta T$ increase from $\sim 4^\circ$ to $\sim 8^\circ C$ from the early to the mid-Holocene while $\Delta \delta^{18}O$ gradients are marked by increased variability but did not change significantly. In contrast, $\delta^{18}O_{sw}$ values and Ba/Ca values indicate a continued strengthening of summer monsoon intensity and maximum Irrawaddy River runoff during the early to mid-Holocene. Minimum $\delta^{18}O_{sw}$ values and maximum Ba/Ca values recorded during the mid-Holocene mark the wettest period in the Andaman Sea of the past 54 krs. A similar mid Holocene peak wetness was observed in speleothem records from northern Borneo, which has been linked to a southward shift in the mean position of the ITCZ thereby crossing the equatorial west Pacific $\sim 5$ kyr ago in response to precessional forcing (Partin et al., 2007). However, precessional forcing with a minimal lag would have resulted in the SAM maximum occurring considerably earlier between 10 to 8 kyr as seen in several palaeo precipitation records from north of the Equator (e.g. Stott et al., 2004; Fleitmann et al., 2003). In contrast, our records indicate that SAM precipitation peaked during the mid-Holocene thus lagging precession minimum (at 11.5 ka) and obliquity maxima (at 9.5 kyrs) by several kyrs. Clemens et al. (1991,1996) proposed that this large time lag between maximum NH summer insolation and the timing of strengthened SAM was governed by interhemispheric transport of latent heat from the southern subtropical Indian Ocean. Thus a combined precession and obliquity forcing of the monsoon and latent heat export associated with the two orbital bands would have strengthened SAM precipitation sometime between 9.5 to 3.5 kyrs (Clemens and Prell, 2003). This hypothesis most likely explains the mid-Holocene pacing of the monsoon observed in our records, as well as in several other high-resolution Holocene records from northwest India and Tibet (Bryson and Swain, 1981; Swain et al., 1983; Gasse et al., 1991; Gasse and Van Campo, 1994), the Arabian Sea (Fleitmann et al., 2003; Neff et al., 2001; Schulz et al., 1998), and records from other monsoon regions (Foerster et al., 2012; Weldeab et al., 2014), as well as results from the Paleoclimate Model Intercomparison Project (PMIP3, Braconnot et al., 2102). In particular, model output from the global climate model (MIROC-ESM) most competent in simulating the basic features of present day monsoon circulation (Sharmila et al., 2015) indicates mid-Holocene intensification of the SAM over the northern Indian subcontinent and Irrawaddy catchment (Fig 7a and b). The late (4-2 ka) Holocene Ba/Ca data suggest reduction in riverine runoff while $\delta^{18}O_{sw}$ values remain stable potentially
suggestion a difference in response over the oceans compared to the continent. The late Holocene weakening of the SAM possibly reflects the gradual retreat of the ITCZ in response to decreasing summer insolation (Laskar et al., 2004) as also observed in terrestrial records from India (Bryson and Swain, 1981; Swain et al., 1983; Yadava and Ramesh, 2005).

5. Conclusions

This study demonstrates that SAM climate has undergone abrupt and strong changes due to a complex interplay of orbitally induced insolation forcing and interhemispheric and regional variability. Our $\Delta \delta^{18}O_{sw}$ time series reveals that upper ocean salinity stratification did not change significantly throughout the glacial indicating a limited influence of NH insolation changes. The SAM was significantly weaker during the LGM, which is supported by low inferred river runoff and relatively high SSS. Deglacial Ba/Ca and $\delta^{18}O_{sw}$ trends indicate a gradual monsoon strengthening with the exception of HS1. $\delta^{18}O_{sw}$ values indicate abrupt mixed layer freshening during HS1 consistent with other studies from the Arabian Sea that reported major intensification of the southwest monsoon around 15.5 ka. However, the onset of the last deglaciation shows a gradual SAM strengthening with river runoff increasing beginning ~18kyrs and lead observed Ba/Ca increases the Arabian Sea by ~2-3kyrs. This indicates South Asian Monsoon climate dynamics are more complex than the simple N-S displacement of the ITCZ following insolation changes. Early to mid-Holocene SAM variability is characterized by a gradual intensification of monsoon rainfall while upper ocean stratification remained relatively constant. Peak monsoon strength during the mid-Holocene in the Andaman Sea is in agreement with records obtained from other monsoon regions and was most likely linked to combined precession and obliquity forcing, which is consistent with model simulations.

Acknowledgments

Part of this work was funded by the German Science Foundation, DFG, grant HA 5751/3-1. B.N. Nath thanks the Director, CSIR-National Institute of Oceanography, Goa, for the permission to publish this paper and Ministry of Earth Sciences (Government of India) for the ship time. Support from CSIR Networked Projects GEOSINKS and GENIAS is acknowledged. This is NIO contribution No. ---. We thank Nadine Gehre for laboratory assistance for Mg/Ca cleaning and Fynn Wulf for stable isotopes measurements.

Age model

The age model for core SK 168/GC 1 was developed using Accelerator Mass Spectrometer (AMS) \textsuperscript{14}C dates of planktic foraminiferal tests (mixed Globigerinoides ruber and Globigerinoides sacculifer) and correlation of the oxygen isotopic values of \textit{G. ruber} with the standard oxygen isotopic curve of Martinson et al. (1987). AMS \textsuperscript{14}C ages were determined at five different intervals at NOSAMS facility at WHOI, USA and converted to calendar age using CalPal 2007 Programme (Weninger et al., 2007; http://www.calpal.de). The AMS \textsuperscript{14}C ages were corrected assuming a reservoir age of 460 years following Butzin et al. (2005). Assuming constant sedimentation rates between the calibrated ages, calendar ages have been assigned by interpolation/extrapolation. The average sedimentation rate for the core is 7.79 cm/ka and vary between ~3.65 and ~10.20 cm/kyr during the MIS3/MIS 2 and the Pleistocene-Holocene transitions respectively. Further comparison of \textit{G. ruber} oxygen isotopic record of core SK 168/GC with LR04 tuned (Lisiecki and Raymo, 2005) published benthic records from the eastern Indian Ocean (Bolton et al., 2013) and the Andaman Sea (Ali et al., 2015) confirm the accuracy of the age model (Figure S1).
Planktic foraminiferal Ba/Ca and SSS estimations

Ba/Ca ratio of planktic foraminiferal tests provides a useful proxy to assess past river water discharge into the Ocean and infer paleosalinity changes (e.g. Weldeab et al., 2007). This is based on the fact that dissolved Ba is high in riverine water relative to sea water (Bahr et al., 2013; Hall and Chan, 2004; Schmidt and Lynch-Stieglitz, 2011) and Ba incorporation into foraminiferal shells varies linearly with seawater Ba concentration (Ba$_{sw}$) (Lea and Spero, 1992; Lea and Spero, 1994), independent of environmental changes including PH, temperature, salinity and symbiont photosynthesis (Hönisch et al., 2011). Consequently, foraminifera Ba/Ca (Ba/Ca$_{foram}$) depends only on seawater Ba concentration, and its temporal variation can be used to infer changes in riverine freshwater input. To estimate past SSS change from Ba/Ca$_{foram}$, we use Ba$_{sw}$ and salinity data obtained from the Bay of Bengal (Singh et al., 2013) and calculate Ba/Ca in sea water (Ba/Ca$_{sw}$). Ba/Ca$_{sw}$ is calculated considering the conservative behavior of Ca and linear relationship of Ca with salinity based on the assumption that a salinity of 35 psu corresponds to 10.2 mmol/kg (Weldeab et al., 2007). Ba/Ca$_{foram}$ is calculated from Ba/Ca$_{sw}$ (μmol/mol) using the partition coefficient of D$_{Ba}$ =
0.19 (Lea and Boyle, 1991) and is given us:

\[ \text{Ba/Ca}_{\text{foram}} = D_{\text{Ba}} \times \text{Ba/Ca}_{\text{sw}} \]

We estimate past sea surface salinity (SSS) using \( \text{Ba/Ca}_{\text{foram}} \) and the modern SSS-\( \text{Ba/Ca}_{\text{foram}} \) relationship using 7 data points from a North – South transect in the Bay of Bengal (Figure S2). Six stations from the northern tip of the Bay of Bengal appear to overestimate SSS values and were excluded from the equation. Thus, SSS is calculated from \( \text{Ba/Ca}_{\text{sw}} \) (\( \mu \text{mol/mol} \)) and is given us:

\[ \text{SSS} = -3.7 \times \text{Ba/Ca}_{\text{foram}} + 36.2 \]

The Ba-salinity relationship in the Bay of Bengal – Andaman Sea appears complex with two possible slopes (Fig S2) and six stations from the northern tip of the Bay of Bengal appear to overestimate SSS values in the Andaman Sea and were excluded for our purposes.

Figure S1. Relationship SSS and Ba/Ca in sea water from the Bay of Bengal (Singh et al., 2013).
